#### 2. MATERIAL AND METHODS

### 2.1. VIRUSES (SPIKING TEST SYSTEM)

Sars-Cov-2

INMI (Institut National des Maladies Infectieuses), reference Human 2019-CoV, strain 2019 nCoV/Italy-INMI

#### 2.1.1. Virus stock

Main characteristics of Sars-Cov-2 virus are described in the table below:

Virus	Sars-Cov-2
Family	Coronaviridae
Subfamily/Genus	Coronavirus
Host	Human
Genome	single-stranded RNA
Envelope	Enveloped
Size in diameter	80-120 nm
Resistance to physico-chemical treatment	Medium
Titration cells	Vero Institut Pasteur, Laboratoire de Virologie Medicale

# **2.2. CELLS (TITRATION TEST SYSTEM)** (Freshney R.I., 1989, ATCC)

Study number: 1198/01

The cells are grown in accordance with Texcell's operating procedures TE1002, TE3001 and TE3011.

• Vero cells: (Institut Pasteur, Medical Virology Laboratory) (Simizu B. and Terasima T. 1988; Simizu B. et al., 1967).

Continuous cell line from kidney of an African green monkey.

#### 3. EXPERIMENTS

#### 3.1. PROCESS DESIGN

As requested by the sponsor the process below will be evaluated as one step:

As requested by the sponsor the process below will be evaluated as one step: Haier device

(A) Inactivation

- Virus slide glass preparation with SARS-COV-2
- Place virus slide glass and Haier device into a sealed system
- After the required incubation time (4h, 2h, 1h) the virus slide glass is removed
- virus slide glass in the test group and control group was eluted thoroughly with 10ml eluent, respectively
- Virus titration and calculation virus reduction factor R
   Process Duration (X) = 4h, 2h and 1

#### **Titrations:**

Virus titration will be performed by end-point dilution assay (TCID50) for SARS-COV-2. Samples obtained during the spiking experiments will titrated immediately with the appropriate controls (depending of the Preliminary Assay result).

#### 4. INFECTIVITY METHODS

#### 4.1. TITRATION ASSAY

The samples are titrated according to operating procedure **TE1088**.

#### 4.1.1. Principle of titration

The titration method is a quantitative assay in which the virus titer measurement is based on the detection of virus production in the infected cells, by observation of a specific cytopathic effect.

#### \*Serial dilutions titration

Briefly:

Test sample is diluted with medium by serial 3-fold dilutions (eight replicates are performed for each dilution) across the 96 well plate (sample dilution plate).

Study number: 1198/01 March 09, 2021 Page 5 of 20

Each well from the "sample dilution plate" is then inoculated on the corresponding well of a new plate (sample titration plate).

Cell suspension is added to each well of the "sample titration plate" and the plates are then incubated at appropriate temperature with or without CO<sub>2</sub> atmosphere (depending on viruses). After a period of incubation allowing viral replication and infection of adjacent cells, depending on viruses,

- wells with foci are counted after infection by observation under inverted light microscope.
- or a stain overlay (crystal violet) is added and wells are examined for cytopathic effect. The infected wells show up as clear areas whereas the non-infected wells are stained.

The infectious titer expressed as 50% tissue culture infective dose per milliliter (TCID<sub>50</sub>/mL) is calculated using the Spearman-Kärber formula.

#### \*Large Volume titration (LVT)

LVT assay could be performed (at the sponsor request) in order to improve the detection limit of the assay or the titer of the tested sample. Cells in 96 well plates or flasks (number according to desired sensitivity) are inoculated with a large volume of the lowest non-toxic and non-interfering dilution of the sample.

Cell suspension is then added to each well of the "sample titration plate" and the plates are incubated at appropriate temperature with or without CO<sub>2</sub> atmosphere (depending on viruses). After a period of incubation allowing viral replication and infection of adjacent cells, depending on viruses,

- wells with foci are counted after infection by observation under inverted light microscope.
- or a stain overlay (crystal violet) is added and wells are examined for cytopathic effect. The infected wells show up as clear areas whereas the non-infected wells are stained.

The infectious titer expressed as 50% tissue culture infective dose per milliliter ( $TCID_{50}/mL$ ) is calculated using the appropriate formula.

#### 4.1.2. Titration assay controls

#### \*Negative control N1 (cell reference control)

During titration assay, in each 96-well plate, 8 wells are prepared as cell reference control. These cells are prepared in the same conditions as those used for the titration of the samples generated during the viral clearance experiments except that they are inoculated with unspiked medium.

#### \*Positive reference control (virus reference control)

During each titration assay, a stock of each virus prepared at low final concentration of approximately  $10^5 - 10^7$  TCID<sub>50</sub>/mL (depending on virus) and used as virus reference control is titrated in the same conditions as those used for the titration of the samples generated during experiments.

#### 4.1.3. Spiking experiments controls

#### \*Cytotoxicity test control(s)

The evaluation of the cytotoxic effect is carried out by visual observation under inverted light microscope. The quality of the cell monolayer (confluence, refringence, aspect) of the tested samples is compared with that of the cell reference control N1.

Negative controls (N2 and N3) and each dilution of samples for which no total cytopathic effect is observed are evaluated for cytotoxicity by comparison with the cell reference control N1. Similar serial dilutions as those used for the titration assays are applied.

For a defined sample, the non-cytotoxic dilution is reached when no significant difference is observed in the 3-fold serial diluted sample compared with the cell reference control.

#### \*Storage control(s)

The evaluation of the effect of the storage conditions on virus in the tested sample during the storage at  $\leq$  -70°C is carried out by comparison of the titers obtained in medium and in diluted sample after storage.

This evaluation is carried out with the starting material(s), and/or the final material(s) obtained from the Mock run when the generated samples are stored until titration.

The study is described as follows:

- The starting material and/or the final material is diluted at a defined dilution, and then spiked with virus (positive control or virus stock) at a low final concentration of approximately 10<sup>3</sup>-10<sup>4</sup> TCID<sub>50</sub>/mL.
- In parallel, medium is also spiked with the same virus (positive control or virus stock) to reach the same concentration as the starting material and/or final material samples.

Both storage controls samples are then stored at  $\leq$  -70°C until titration. These storage controls are prepared and titrated with the experiments generated samples

After titration, there is no storage effect on virus, when the difference between the two titers (titer in medium compared with titer in starting and/or final material(s)) is less than or equal to 1Log<sub>10</sub>.

#### \*Viral interference assay(s)

The evaluation of the potential interference of the lowest non-cytotoxic dilution of the sample on virus during the incubation period is carried out by comparison of the results obtained during the titration of the virus stock with medium, and the virus stock with diluted sample (final material/starting material and/or intermediate product).

The evaluation is carried out with the final material(s) (obtained from the mock run).

The results are used for the calculation of the reduction factor of the step.

The study of sample interference on virus titration is described as follows:

- First, the virus reference control (titration reference) at a low final concentration of approximately 10<sup>5</sup>-10<sup>7</sup> TCID<sub>50</sub>/mL, is titrated in the usual conditions i.e. serial 3-fold dilutions using medium as diluting medium
- In parallel, the same virus reference control is titrated by serial 3-fold dilutions using the lowest non-cytotoxic dilution of the sample to be tested as diluting medium.

The evaluation of the potential interference of the lowest non-cytotoxic dilution of the sample with the virus during the incubation period is carried out by comparison of the titers obtained in medium versus titers obtained in diluted sample.

For the defined non-cytotoxic dilution of the sample, there is no interference when the difference between the two titers is less than or equal to  $1\text{Log}_{10}$ . This non-cytotoxic and non-interfering dilution is then used for the calculation of the infectious titer of the sample.

March 09, 2021 Page 7 of 20

# Study number: 1198/01

#### 4.2. ACCEPTANCE CRITERIA OF THE TITRATION ASSAY

During each titration assay, a virus stock prepared at low final concentration of approximately  $10^5 - 10^7$  TCID<sub>50</sub>/mL (depending on virus), is used as reference control.

The titration assay is retained when:

- the cell reference control (N1) for each titration plate is conform to the expected result,
- the infectious titer of the virus reference control obtained is in the expected range.

#### 4.3. **DETERMINATION OF THE VIRAL TITER**

(Schwartz D., 1993; Kaplan M. and Koprowski H., 1973)

Three situations may be predicted concerning the calculation of the viral titer.

Case	Subcase	Titer (T)
Infectious particles detected ≥ 12.5% positive wells/total tested wells		$T = T_{SK}$
Few infectious particles detected < 12.5% positive wells/total tested wells	$T_{MaxL} > dl$ $dl > T_{MaxL}$	$T = T_{MaxL}$ $T = dl$
No infectious particles detected 0% positive well/total tested wells		T < dl

with:

T = titer retained for the calculation of the reduction factor

 $T_{SK}$  = infectious titer using the simplified Spearman-Kärber formula (Section 2.3.1)

 $T_{MaxL}$  = infectious titer using the Maximum likelihood estimation (Section 2.3.2)

dl = detection limit using the Poisson formula with 95% precision (Section 2.3.3)

#### 4.3.1. Calculation of the TCID<sub>50</sub> using Spearman-Kärber formula

The TCID<sub>50</sub> is evaluated by quantitative assay and defined as the virus dose capable of infecting 50% of the inoculated cultures.

The viral titer, T, expressed as the 50% tissue culture infective dose per milliliter (TCID $_{50}$ /mL), is defined by its mean value, m(T), and its confidence interval.

m(T) can be calculated according to the following formula:

$$m(T) = \frac{1}{Vo} 10m(a)$$

with  $v_0$  = volume per replicate

"a" is also defined by its mean, m(a), and its standard deviation, S(a).

The viral titer can be calculated using Spearman-Kärber (SK) formula (Payment P. and Trudel M. 1993).

\*This method is applicable firstly, in situations where cytopathic effect is observed, ranging from 0% to 100% of positive replicas per dilution in a same titration plate.

 $m(a) = T_{SK}$ , and S(a) is calculated using the following simplified Spearman-Kärber formula

Study number: 1198/01

$$m(a) = T_{SK} = -a_0 + \frac{k}{2} - k \sum_{i} p_i \quad \text{and} \quad S(a)^2 = k^2 \sum_{i} \frac{p_i (1 - p_i)}{n_i - 1}$$

with:

 $a = Log_{10}$  of the titer relative to the test volume

 $a_0 = Log_{10}$  of the reciprocal of the lowest dilution for which all wells are positive

 $k = Log_{10}$  of the dilution factor

 $p_i$  = proportion of positive wells at the non-cytotoxic dilution  $d_i / r_i$ 

 $r_i$  = number of positive wells at the non-cytotoxic dilution  $d_i$ 

 $n_i$  = number of replicates at the non-cytotoxic dilution  $d_i$ .

With a 95% precision, the confidence interval of "a" is the following:

$$a^{\min} \le a \le a^{\max}$$
 with:  $a^{\min} = m(a) - 2 S(a)$   
 $a^{\max} = m(a) + 2 S(a)$ 

With a 95% precision, the confidence interval of the titer T is the following:

$$T^{min} \leq T \leq T^{max} \text{ with:}$$
 
$$T^{min} = \frac{1}{Vo} 10^{amin}; T^{max} = \frac{1}{Vo} 10^{amax}$$

The dilutions of the samples retained for the calculation of the infectious titers are those for which no cytotoxicity is observed.

\*Secondly, when less than 100% but  $\geq$  12.5% of positive replicas per dilution is obtained for the lowest non-cytotoxic dilution tested, the virus titer is calculated assuming that the sample contains sufficient virus to infect 100% of tested wells at the previous serial dilution (worst-case).

#### \*Total virus load

The viral load L is defined by its mean value, m(L), and its confidence interval.

$$m(L) = \frac{m(T)V_t}{c}$$

$$L\min \le L \le L\max: \qquad L^{min} = \frac{T^{min}V_t}{c} \text{ and } L^{max} = \frac{T^{max}V_t}{c}$$

with:

c = concentration factor of the ultracentrifugation (c = 1 when the samples are not ultracentrifuged).

 $V_t$  = total volume of the sample during the scaled down process.

March 09, 2021 Page 9 of 20

Study number: 1198/01

#### 4.3.2. Large Volume Titration assay: Maximum Likelihood estimation

During LVT assay, when few positive wells are detected (< 12.5% of all tested wells), viral titers (T<sub>MaxL</sub>) in samples are calculated according to Maximum Likelihood estimation (Agut H., Calvez V., Barin F, 1997) as follows:

$$T_{MaxL} = (Ln (N/P) x d x (1000/v)) / Ln2$$

with:

 $T_{MaxL}$  = titer relative to the test volume (TCID<sub>50</sub>/mL)

N = number of all tested wells

P = number of negative wells

d = non-cytotoxic dilution factor of the sample

v = tested volume per well

 $Ln2 \approx 0.69 = corrective factor to convert PFU/mL into TCID<sub>50</sub>/mL.$ 

When significant positive wells are detected (>12.5% of all tested wells) viral titers ( $T_{MaxL}$ ) in samples are calculated using the Spearman-Kärber formula as described above.

#### \*Total virus load

The viral load L is defined by its mean value,  $m(L_{MaxL})$ .

$$m(L_{MaxL}) = \frac{m(T_{MaxL})V_t}{c}$$

with:

c = concentration factor of the ultracentrifugation (c = 1 when the samples are not ultracentrifuged).

V<sub>t</sub> = total volume of the sample during the scaled down process.

#### 4.3.3. Detection limit of titration assay

When a sample contains a low concentration of infectious virus and only a fraction of the sample is tested for titration, there is a probability that the result of the tested fraction will be negative due to random (and unequal) distribution of the virus throughout the sample.

The detection limit, dl, for the titration assay corresponds to the lower theoretical titer which results in the detection of one infectious particle in one of the replicates performed. Since the infectious particle would be detected in a volume  $V_c$  (mL) of the dilution  $d_c$ , the detection limit, dl, is calculated with a 95% precision according to the Poisson formula (Löwer J., 1991):

$$p(95\%) = e^{-dl} [V_c d_c] = 0.05$$

i.e. 
$$dl = \frac{-\ln{(0.05)}}{V_c d_c}$$

with:

 $V_c = [v_0 \ n_c]$ 

v<sub>o</sub> = volume per replicate

 $n_c$  = number of replicates at non-cytotoxic dilution  $d_c$ 

dl = detection limit

The non-cytotoxic dilution of the samples for which no positive wells are detected is then retained for the calculation of the infectious titer using the Poisson formula.

The infectious titers calculated with the Poisson formula are expressed as PFU/mL and are divided by ln2 to be converted into  $TCID_{50}/mL$ .

#### \*Detection limit of the viral load of a whole fraction

The detection limit, DL, is the minimal viral load which could be theoretically detected in the total volume of a fraction belonging to the scaled down process.

DL is calculated according to the following formula:

$$DL = \frac{dl \, V_t}{c}$$

with:

c = concentration factor of the ultracentrifugation (<math>c = 1 when the samples are not ultracentrifuged),

Vt = total volume of the sample during the scaled down process,

dl = detection limit for a titration assay.

The detection limit for the pre and post-treatment material are DL<sub>i</sub> and DL<sub>f</sub> respectively.

#### 5. REDUCTION FACTOR CALCULATION

In accordance with the regulatory documents, the virus reduction factor (R) of an individual purification or inactivation step is defined as the Log10 of the ratio of the virus load (Li) in the pre-treatment material (starting material) and the virus load (Lf) in the post-treatment material (final material) which is ready for use in the next step of the process.

R is defined by its mean, m(R), and its confidence interval, [Rmin  $\le$  R  $\le$  Rmax]. If Rmin and/or Rmax is < 0 (negative value), then m(R) will present as  $\approx$  0 without confidence interval.

Different cases have to be considered related to the effect of the pre-treatment material on the virus.

#### \*Case 1

A studied manufacturing process step consists in the monitoring of a viral inactivation directly linked to a solution used during the process ("in process fraction", sanitization solution, etc.). In other terms, a putative virucidal effect associated with a solution is evaluated in a kinetics study.

Study number: 1198/01 March 09, 2021
Page 11 of 20

#### \*Case 2: Treatment reduction factor calculation m(Rt)

The pre-treatment material has no significant inactivating effect, i.e. the mean reduction factor,  $m(R_0)$  is lower than or equal to 1.  $m(R_0)$  is defined as the  $Log_{10}$  of the ratio of the virus load in the medium  $(L_{cm})$  and the virus load in the pre-treatment material  $(L_i)$ .

In this case, the reduction factor of the step corresponds to the reduction factor of the treatment  $m(R_t)$ .

#### \*Case 3: Clearance factor calculation m(R)

The pre-treatment material has a significant inactivating effect (excluding Case 1) i.e. the mean reduction factor,  $m(R_0)$  is higher than 1.

- In a first approach, the clearance factor of the step, m(R), is calculated as the sum of the reduction factor associated with the initial inactivating effect, m(R<sub>o</sub>), and the reduction factor of the treatment, m(R<sub>t</sub>). The initial load is the virus load in medium (L<sub>cm</sub>).
- In a second approach, the reduction factor of the treatment, m(R<sub>t</sub>) is calculated with the virus load in the pre-treatment material (L<sub>i</sub>).

#### In practice,

- if the volume of post-treatment material  $(V_f)$  = volume of pre-treatment material  $(V_i) \pm 5\%$  (v/v), the reduction and clearance factors are calculated with viral titers and then X = T.
- Otherwise, the reduction and clearance factors are calculated with viral loads and then X = L.

CASES	SUBCASES	EVALUATION OF THE REDUCTION FACTOR R <sub>t</sub> AND CLEARANCE FACTOR (R)
Case 1		R is evaluated according to the three subcases of Case 2, with $X_i = X_{cm}$
Cara 2	$m(x_f) < DL_f$	$R_t > Log_{10}\left(\frac{m(X_i)}{DL_f}\right)$ with $Rmin \le R_t \le Rmax$
Case 2 $m(R_0) \le 1$	$\begin{aligned} & X_i^{min} \ge X_f^{max} \\ & X_i^{min} < X_f^{max} \end{aligned}$	$m(R_t) = Log_{10}\left(\frac{m(X_i)}{m(X_f)}\right)$ with $Rmin \le R_t \le Rmax$
	$X_i^{min} < X_f^{max}$	$m(R_t)$ is calculated according to subcase 2 $R_t \approx 0$ if Rmin, $R_t$ or Rmax < 0 (negative value)
Case 3	$m(X_i) < DL_i$	$R_t$ cannot be evaluated $R_o \ge Log\left(\frac{m(X_{cm})}{DL_i}\right) \text{ with } Rmin \le R_o \le Rmax$
$m(R_0) \ge 1$	$m(X_i) \geq DL_i$	$\begin{aligned} R_t \text{ can be evaluated at sponsor request, otherwise } R &= R_t + R_o \text{ is calculated} \\ R \text{ is evaluated according to the three subcases of Case 2 with } X_i &= X_{cm} \\ m(R_o) &= Log_{10}\bigg(\frac{m(X_{cm})}{m(X_i)}\bigg) \text{ with } Rmin \leq R_o \leq Rmax \end{aligned}$

 $X_i$  = initial sample titre (Ti) or load (Li)

 $X_f$  = final sample titre (Tf) or load (Lf)

 $X_{cm}$  = culture medium titre (Tcm) or load (Lcm)

m(X) = mean titre or load

 $Rmin = R - 2 \sqrt{var Ti + var Tf}$ 

 $Rmax = R + 2 \sqrt{var Ti + var Tf}$ 

Var = Variance = 
$$S(a)^2 = k^2 \sum_{i=1}^{\infty} \frac{p_i(1-p_i)}{n_i - 1}$$

with:

- k = Log of the dilution factor

p = proportion of positive wells at the non-cytotoxic dilution d / r
 r = number of positive wells at the non-cytotoxic dilution d

n = number of replicates at the non-cytotoxic dilution d.
